MULTIPLE MESON PRODUCTION IN EMULSIONS EXPOSED TO THE BEVATRON BEAM

William R. Johnson

Radiation Laboratory, Department of Physics
University of California, Berkeley, California

May 3, 1955

ABSTRACT

Stacks of 600-micron Ilford G.5 stripped emulsions have been exposed to the internal beam of the Bevatron at three energies: 3.2, 4.8, and 5.7 Bev. Shower-particle production has been investigated at these energies. (A shower particle is defined as one whose grain density is less than 1.4 times minimum.) At each energy 114 events which had beam protons for primaries were found by area scanning. The average shower-particle multiplicities per event were found to be 0.94 ± 0.09, 1.30 ± 0.11, and 1.62 ± 0.11. These results are compared with similar observations by cosmic-ray workers. The various theories of meson production are reviewed and Fermi's calculations for Cosmotron energies have been extended to the energies of this experiment. Production differences in heavy and light nuclei are discussed and compared.

PREFACE

Multiple meson production has been the subject of several papers in recent years and, in the higher energy ranges, cosmic-ray observations have until recently been the only way to compare theory with experiment. The new high-energy particle accelerators, the Cosmotron and Bevatron, accelerate nuclear particles to energies comparable to those found in cosmic rays, and can be used for experimental investigations of meson production.

One method of investigating the interactions of energetic partides--nuclear emulsion technique--has been greatly expanded recently with the development of electron-sensitive emulsions. Detailed observations can be made on such events as nuclear encounters, decays, and scatterings. Emulsions are a versatile tool of physical research and have been used by workers in many fields. In particular, cosmic-ray investigators have made detailed observations of the number of shower particles resulting from the disintegrations of atoms in the emulsions.

It is the aim of this paper to describe observations made in emulsions exposed to the proton beam of the Bevatron and to discuss the theoretical aspects of the interactions that are believed to occur in nucleon-nucleon collisions. Exposure and development techniques are discussed and results are compared with cosmic-ray work in the same field.

The writer wishes to thank Dr. Warren Chupp for his suggestions concerning the problem and informative discussions during the work and the preparation of this paper. He also wishes to thank Drs. Gerson and Sulamith Goldhaber for the use of emulsions from their stacks and for informative discussions of the problem and this paper, Dr. Edward Milne for his review of this paper, Dr. Joseph V. Lepore for a discussion of his nuclear model, Mr. Joseph Lannutti for his unpublished data on prong distributions and instruction in development techniques, and Mrs. Marjorie Hirsch for help with this manuscript.

This work was carried out under the auspices of the U.S. Atomic

Energy Commission at the Radiation Laboratory of the University of California while the author was assigned there from the U.S. Naval Postgraduate School.

CHAPTER I

INTRODUCTION

1. Nuclear Forces.

The structure of the atomic nucleus and the nature of its binding forces are the foremost problems of the nuclear physicist. In early stages of the studies of nuclear forces it was hoped that the development of nuclear physics would parallel that of atomic physics. Investigations of the smallest atomic unit, the stable hydrogen atom, disclosed the nature of atomic structure and forces. A complete theory substantiated by experimental facts was then evolved. In the study of the smallest unit in which nuclear forces play a part, the deuteron, it has not been possible to accumulate sufficient data to formulate a consistent general theory because there is essentially only one bound state, not the several states found in the structure of the hydrogen atom. The study of larger nuclei introduces the complexities of the many-body problem and therefore a complete analysis in the general case is not possible.

In quantum electrodynamics each particle interacts only with the electromagnetic field. The interaction between two particles is through the field and can be explained in terms of an exchange of discrete energy quanta between the interacting particles. The quanta are the zero-rest-mass photons of the electromagnetic field. Yukawa suggested that forces between nucleons might be due to a similar field, now identified as the meson field. A characteristic difference between nuclear forces and electromagnetic forces is that nuclear forces act only at very short distances (of the order of 10^{-13}cm), whereas the electromagnetic forces have no characteristic length.

The range R of nuclear forces is the maximum distance at which two nucleons can interact as a result of one particles emitting a virtual meson which is then absorbed by the other. If this virtual meson travels with the velocity of light, it exists for a time

$$\Delta t = R/c.$$

During the existence of the meson the energy of the system is increased by

$$\Delta E = m_\pi c^2 .$$

This, however, is a violation of the energy conservation law and by the uncertainty principle the violation can exist for only a time consistent with the uncertainty of measurement

$$\hbar = \Delta E \cdot \Delta t = m_\pi c R.$$

Therefore the mass of the meson field quantum is

$$m_\pi = \hbar / Rc = 300 \text{ electron mass units.}$$

This quantum is analogous to the photon of the electromagnetic field.

When the wave-particle dualism of nature is considered, quanta can be regarded as waves that can be emitted from the nucleus. The waves are concentrated within the nuclear volume and their constructive interference represents particle emission. These quanta, pions, are thought to be the building blocks of nuclear matter, and are the source of difficulties that arise when attempts are made to formulate a nuclear theory along the same lines as the electromagnetic theory. Wave lengths of pions are much shorter than those of most photons, so that higher energies are required for the perturbing particles. When higher energies are used, the creation of mesons introduces a many-body problem and complicates field-theory predictions.

2. High-Energy Nucleon-Nucleon Encounters.

The domains involved in the investigations of nuclear forces are so small that answers must be derived indirectly from observations of events that occur when a nucleus is perturbed by a high-energy particle. Cloud chambers and the various types of fast electronic counters had been the principal instruments for the study of nuclear forces prior to the development of sensitive nuclear emulsions. High-energy particle accelerators and cosmic rays have been used as sources of primary nucleons to strike target nuclei in emulsions. The incident nucleon, in the Bev range, makes one or several collisions with the individual nucleons of the nucleus within 10^{-23} second. This time is approxi-

mately that required for a particle traveling with the speed of light to traverse the nucleus. Compared with the period of motion of nucleons the collision time is short, because of the short DeBroglie wave length of the incident particle. The short wave length localizes the particle to a small region in space and makes encounters with individual nucleons possible. In effect, there is a series of collisions or a cascade process within the nuclear volume which may be radiative or elastic. In radiative collisions various types of quanta (mesons) may be radiated. In both types of collisions recoil nucleons are produced, which may either escape immediately or interact further with other nucleons (and may subsequently escape after having undergone one or more encounters).

Studies of collision processes can be approached in different ways. Each approach will add to the store of physical knowledge and the final results may contain explanations for the many unanswered questions. One phase of the problem is the process of meson production and its variation with incoming particle energy. Theories have been developed to the extent that direct comparison with experiment can be made. Cosmic-ray workers have investigated production in nucleon-nucleon collisions and, with the advent of the high-energy proton-synchrotrons at Brookhaven and Berkeley, physicists have begun similar investigations using pure proton beams.

This paper is concerned with multiple meson production by protons in the Bev range and includes the following aspects of the problem: the theoretical proposals that have been advanced to explain the processes involved, the use of the Bevatron and nuclear emulsions to produce and detect mesons, the results of a detailed study of meson production, and a comparison of these results with theoretical predictions and observations made on production from cosmic rays. This study represents an addition to previous work because pure proton beams at known Bev energies were used whereas previous investigations were carried out with primaries that were an admixture of protons and pions.

CHAPTER II

THEORIES OF MESON PRODUCTION AND STAR FORMATION

1. General.

Theories relating to meson production in high-energy nucleon-nucleon collisions may be divided into two general classes, plural and multiple. Fundamentally these two theories differ in principle. In the plural theory of Heitler and Janossy [13, 14] the radiation-damping effect is assumed to be so strong that only a single meson can be produced per collision in the majority of cases. This assumption is postulated on the basis of the strong meson coupling of the Yukawa theory. The coupling is so postulated that a single meson can be emitted if the energy is supplied and is of the proper order of magnitude to account for the nuclear forces. The multiple theories of Heisenberg [12], Lewis et al. [19], Fermi [5], and Lepore [18] assume that several mesons can be created in a single collision so inelastic that the primary does not have sufficient energy to create more mesons. In a large nucleus when there is enough energy available both theories predict a meson shower and differences can not be noted. On the other hand, when a nucleus of low atomic mass number is struck, very different results are predicted.

2. Plural Theory.

In the pure form of the plural theory Heitler and Janossy assumed (a) in each nucleon-nucleon collision only one meson is produced, (b) the mean free path for a collision is of the order of the internucleon distance, and (c) the nucleus is completely transparent to the created mesons and recoil nucleons. The total plurality is then given by the number of encounters that the primary nucleon makes in passing through the nucleus.

In each collision the primary loses a fraction σ of its kinetic energy; of this, the recoil nucleon takes a fraction α and the created meson is left with the remainder $\sigma - \alpha$. There is a definite cutoff energy below which meson production ceases. After n meson-pro-

ducing collisions, the primary has an energy of $(1-\sigma)^n E_o$ and n recoil nucleons have been produced with energies of $(1-\sigma)^{n-1} E_o$. As long as the primary energy is greater than the cutoff energy more mesons will be created. From these considerations Heitler estimates the total number of charged and neutral mesons created to be

$$N_s = \frac{\log (\gamma_p - 1) - \log (\gamma_c - 1) + 1}{-\log (1-\sigma)}, \qquad (1)$$

where γ_p is the primary energy in rest mass units, γ_c is cutoff energy in the same units. When only those mesons with kinetic energy greater than 80 Mev are considered, γ_c equals 3.1. Heitler assumed $\sigma = 0.25$ and $a = 0.125$. If there is symmetrical charge distribution in mesons, two-thirds of the created mesons must be charged.

Heitler's theory appears to give reasonable results except at high primary energies, where the recoil nucleons and created mesons have energies above the meson-production threshold. These particles could themselves act as primaries in generating more mesons. In the modified plural theory the same authors included the possibilities of production by second and higher generations.

3. Multiple Theories.

The multiple theories start with the assumption of possible production of more than one meson per collision, and take into account the opacity of the nucleus to the created mesons. The various theoreticians use different approaches, however, in analyzing the collisions.

Lewis et al. use the problem of electromagnetic radiation as an analogy and make assumptions that (a) collision time is short compared to periods of emitted radiation, (b) effects of the emitted radiation, particularly its recoil, may be neglected, and (c) components of the radiation field for which these considerations are satisfied are the only ones that need be considered. When these conditions are fulfilled, the radiated spectrum is the difference between the quasi-static field of the radiator before collision and the field after colli-

sion. The conditions apply to the most intense fields closest to the nucleons, therefore the collision problem can be considered only for primary energies greater than 100 Bev. In effect, the emission mechanism is very similar to that in the case of ordinary bremsstrahlung, where the radiated electromagnetic field can be though of as the difference between the quasi-static field of the incident electron and that of the scattered electron.

Heisenberg describes a high-energy collision by assuming that the pion fluid surrounding the nucleus is set into motion by the impact energy. In order to estimate energy distribution he uses qualitative ideas of turbulence; these ideas represent an approach to thermal equilibrium in a fluid. Spreading of the energy of motion into many states of larger and larger wave number is postulated. The total number of mesons produced will then vary with primary energy and inelasticity of the collision. The inelasticity K is defined as the ratio of the energy radiated as mesons in the center-of-mass system to the maximum amount of energy available in this system.

The value of K does not come directly from the theory. At high primary energies the mean value of K must be near unity, according to considerations of equipartition of momentum between nucleons and pions. In the lower energy regions K varies with energy and its value must be determined experimentally.

Fermi goes one step further than Heisenberg and assumes that statistical[1] equilibrium has been reached before mesons are emitted because the interactions taking part in meson production are so strong. According to Fermi, when two nucleons collide with high center-of-mass energies, the energy is localized in a small volume surrounding the nucleons. This spherical volume for interaction has a radius equal to the meson Compton wave length, $\hbar/m_\pi c$, and is flattened in the direction of motion by the Lorentz contraction. Since statistical equilibrium is reached in this volume, the number of states available to the e-

1. See Milburn [22] for a review article on statistical meson production theories.

mitted particles in phase space can be calculated from the principles of statistical mechanics and thereby one can determine the relative multiplicity and momentum distributions.

Fermi has calculated statistical weights for each state dependent upon charge distributions, but neglected interference effects and angular momentum states. Nucleons are treated as monrelativistic and pions as very relativistic, and momentum is not conserved among pions. His results give the relative probability for the production of n mesons as a function of energy,

$$f_n(w) = \left[\frac{251}{w}(w-2)^{\frac{3}{4}}\right]^n \Big/ \left[\frac{3}{2} \times \frac{5}{2} \cdots \frac{6n-1}{2}\right], \qquad (2)$$

where w is the total energy of the colliding nucleons in the center-of-mass system in units of nucleon rest energy.

Fermi supplemented his original paper with a paper on pion production at Cosmotron energies [67], in which he considered the effects of charge conservation for the nucleons and pions, a consideration neglected in the earlier theory. He made computations for low-multiplicity production--three pions or less. The number of possible types of transitions was restricted by requiring that isotopic spin be conserved. For any statistical consideration of a high-energy collision, all final states are formed with a probability proportional to the weight of that state, providing it can be reached from the ground state without violating the laws of conservation of energy, momentum, angular momentum, charge, and isotopic spin. Fermi's calculations for Cosmotron energies can be extended to Bevatron energies to give multiplicities expected in the experiment, so a rather complete discussion follows.

The initial state before a collision of two nucleons may have either isotopic spin $T = 1$ or $T = 0$; consequently, only those final states with isotopic spin one or zero need be considered. Each state has a number of charge possibilities. After Fermi, let p_n be the number of possibilities for $T = 1$ and q_n be the number of possibilities for $T = 0$.

In a collision of two protons the initial isotopic spin state is

T = 1; therefore the most abundant final state will be the same. Its probability will be proportional to f_n (from Eq. (2)) and p_n. In a collision between a proton and neutron the initial states are T = 1 and T = 0, so the final states will also be T = 1 and T = 0. For T = 0 the probability would be as above, substituting q_n for p_n. The resultant final probability is an average of the two. Expressions have the following form:

$$P_n = p_n f_n \Big/ \Sigma\ p_n f_n, \qquad Q_n = p_n q_n \Big/ \Sigma\ q_n f_n. \tag{3}$$

The charges of the pions, as well as their multiplicity, must be known before the above figures can be compared with experiment, because only charged mesons can be observed directly. The number of neutrals must be subtracted from the theoretical values before comparison can be made. The numbers p_n and q_n may be subdivided into states corresponding to possible charges and their weights can be determined. These values are tabulated by Fermi for p-p and p-n collisions and are used in calculations of the multiplicities given in Table IV, Chapter VII.

Lepore has used a statistical model and followed Fermi in assuming the establishment of a state approximating equilibrium before meson emission. Probability of disintegration into the various possible modes is proportional to a relative extension of accessible phase space. His interaction volume does not have the Lorentz contraction of the Fermi model, but he obtains what might be considered a uniform shrinkage of the configurational volume with increasing energy by energy-dependent cutoffs.

4. Star Formation.

In the theoretical aspects of a collision considered in the earlier sections only the mechanisms responsible for meson formation have been discussed. This is the initial step in star formation and takes place in 10^{-23} second. The complete nuclear disintegration involves emission of a few particles which may include the primary nucleon, knock-on nucleons and created mesons, and a number of slow particles with an average energy of 10 Mev. If the energy distributions were

plotted, there would not be a break between the two groups, but the first group would appear as a high-energy tail on the second.

The slow particles arise as a result of the nuclear excitation by the fast particles of the first group, and their emission is analogous to evaporation. The evaporation theory as first postulated by Bohr was extended by Harding et al. [11] to low-energy particles from stars. They found, using the Fermi gas model of the nucleus and making allowance for cooling and barrier penetration, that the theory made reasonable predictions of the observed energy spectrum. Using a nuclear model with mass near 100, LeCouteur [17] extended Harding's work by taking into account the thermal expansion and the neutron excess of the residual nucleus. He obtained energy distributions of evaporated particles and calculated probabilities for emission of protons, neutrons, deuterons, tritons, He^3, and alpha particles as a function of excitation energy. The assumption that the nucleus always remains in an approximate state of thermal equilibrium requires that excitation energies be less than 600 Mev, thereby restricting the validity of the calculations to a maximum star size of about fourteen prongs. Since the light nuclei were excluded in the basic model, LeCouteur's theory is strictly applicable only to stars having between six and fourteen prongs.

Fujimoto and Yamaguchi [8, 9] have considered the same problem, taking into account the changes in binding energy of nuclear particles during evaporation. They envisage a step-by-step process in which thermal equilibrium is reached between each particle emission.

The general mechanism as postulated by all workers is that the excitation energy results from the kinetic energy of nucleons that have undergone collisions but do not have enough energy to escape immediately. The kinetic energy distributes itself statistically, raising the nuclear "temperature" as a whole and causing evaporation. It is estimated that the evaporation processes occur within approximately 10^{-16} second after the collision.

CHAPTER III

THE BEVATRON AS A SOURCE OF HIGH-ENERGY PROTONS

1. Acceleration of Protons.

In order to investigate disintegrations resulting from high-energy nucleon-nucleon interactions, balloons have been flown with emulsions and cloud chambers into the upper atmosphere where there is a flux of very energetic pions and nucleons. High-energy accelerators have been developed to provide intense controlled particle beams at energies comparable to median values found in cosmic rays. In this experiment the Berkeley Bevatron has been used as a source of energetic protons. A short discussion of its characteristics is appropriate.

The Bevatron is a proton synchrotron which utilizes the principle of "phase stability" as evolved by Veksler and McMillan. (Bohm and Foldy discuss this principle in detail in their article on "Theory of the Synchrotron" [24] .) The angular velocity of a particle with a charge e and relativistic mass m in a magnetic field H is give by

$$\omega = eH/mc = ecH/E \qquad (4)$$

The phase-stable particle will stay in or near its stable orbit even though small disturbing forces are applied to it. This implies that the acceleration can be accomplished by slowly varying the magnetic and electric fields.

Equation (4) can be rewritten in the following form:

$$cp/eH = r = \text{constant for a synchrotron.} \qquad (5)$$

Equation (5) then represents the relationship between momentum and magnetic field necessary in order to keep a particle in its orbit. Differentiation of Eq. (5) gives the relation between the incremental values:

$$\Delta p/p = \Delta H/H. \qquad (6)$$

The particle orbit is stable and will follow any slow, or adiabatic, variation of the magnetic field with time in which $\Delta H/H \ll 1/\omega$. In order to provide focusing forces as well as satisfy conditions for phase stability, the magnetic field must be designed with the proper spatial variation. This variation is expressed by the logarithmic field index n.

$$H = H_o \left[r/r_o\right]^{-n} \quad \text{or} \quad n = -\left[r/H \cdot dH/dr\right] \; ; \; 0 < n < 1 \; n \neq 0.5 \; . \; (7)$$

The particle will not remain exactly in the orbit described by Eq. (5), but will execute slow variations about it. The variations are a function of n and ω, and their amplitude varies inversely with the square root of the magnetic field [15, 16] .

The theoretical aspects of charged-particle motion discussed in the previous paragraphs establish the basic requirements for a proton synchrotron: a means of supplying energy to a particle in small steps and a means of guiding it over the path to be followed while gaining energy. The first is done by keeping the accelerating system in an orbital path which the particle uses many times. The second is obtained by having a circular magnet wherein the field decreases with increasing radius. The particle can have its energy increased by changing the frequency and field as indicated by Eq. (4). With the machine radius selected as a design constant, Eq. (5) shows that maximum momentum (or energy) is a function of the field obtainable. The field maximum is limited by such design considerations as magnet size, aperture, and cost.

In the Bevatron the particle trajectory is through four annular quadrants which comprise the magnet. The quadrants are connected by four straight sections which serve to give a field-free space for location of the accelerating electrode, proton injector, vacuum pumps, targets, etc.

Figure 1 is a schematic representation of the Bevatron, showing dimensions and relative locations of the major components. Table I gives Bevatron Statistics.

cost.

Table I

Bevatron Statistics

Radius of equilibrium orbit	50 ft.
Length of straight sections	20 ft.
Size of beam aperture	1 ft. by 4 ft.
Injection energy	9.8 Mev
Maximum final energy	6.3 Bev
Initial accelerating frequency	~ 356 kc
Final accelerating frequency	~ 2,500 kc
Initial field	~ 300 gauss
Peak field	~ 15,870 gauss
Magnet cycle	6 sec
Field index	$0.53 < n < 0.73$
Accelerating time (rising magnetic field)	1.75 sec
Repetition rate	6 pulses/min
Energy gain/turn	1.5 kev
No. of protons injected	$\sim 10^{13}$
No. of protons reaching maximum energy (a)	$\sim 10^{10}$
Beam cross section after injection	1 ft. by 4 ft.
Final beam cross section	~1.5 in. by 4 in.
Operating pressure	10^{-5} mm Hg
Peak magnet power	100,000 kva

a - The beam intensity is reduced for emulsion exposures in the internal beam.

Protons must be injected at the proper energy and radial position commensurate with the initial field and accelerating frequency in order to stay within the annular magnet sections. After injection H and ω are increased until the particle reaches desired energy. The desired energy can be chosen by the selection of an acceleration (rf) field turn-off time. After rf turnoff H continues to increase, causing the equilibrium orbit to shrink. The next sequence of events depends on the desired use of the beam.

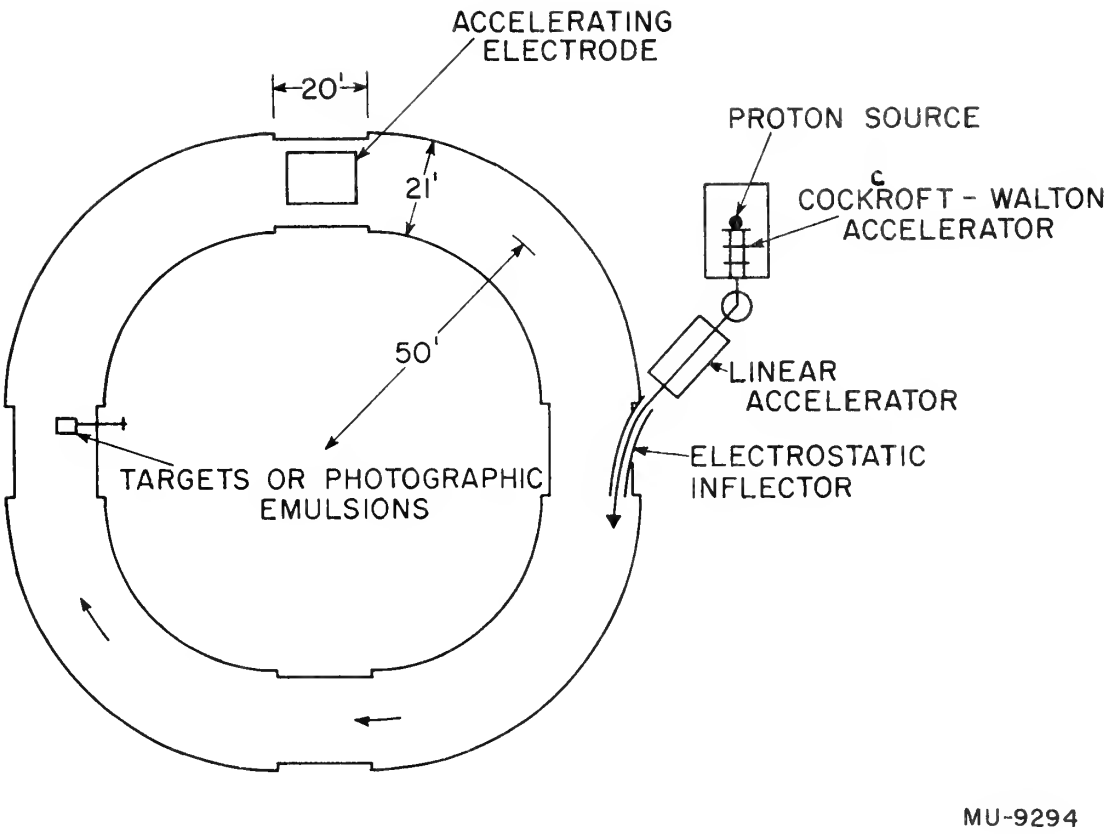

Fig. 1. Schematic of the Bevatron

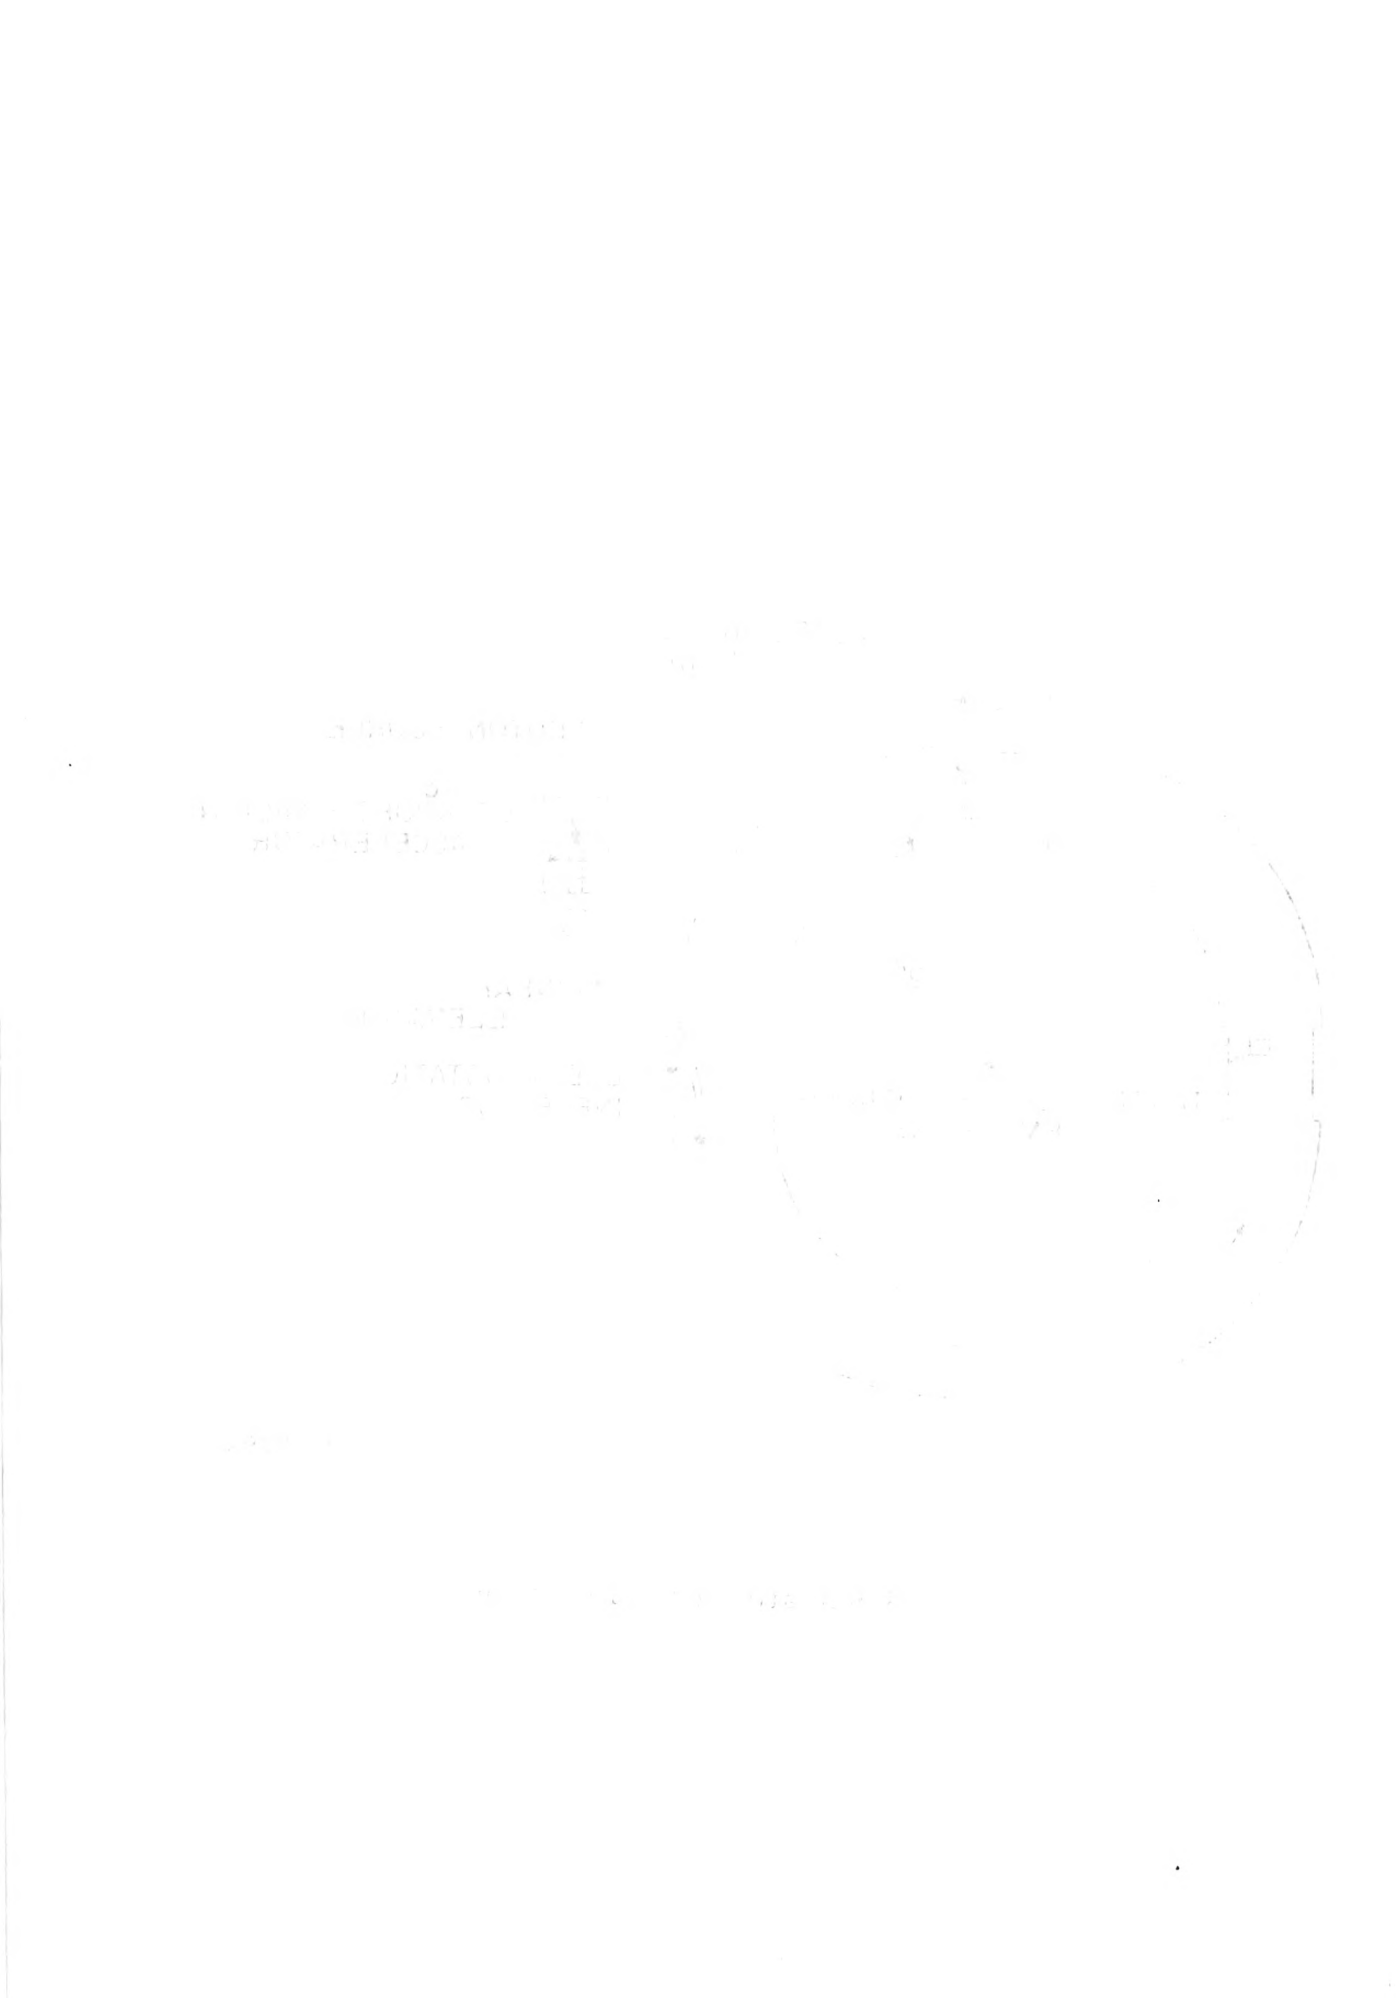

2. Using the Internal Proton Beam.

Internal exposures in the vacuum system were made in this experiment by direct bombardment of emulsion targets or allowing the beam to penetrate a lip target extending one or two centimeters from the edge of the emulsion stack. The lip serves to damp out radial oscillations and increase the spacing between successive passages of the beam. The internal beam is also used for external exposures by putting a target into the beam and observing secondary particles created. Thin windows are located so the target can be viewed from various detector stations where analyzing magnets and collimated beams can be used for charge, mass, and momentum selection.

The inner radial surface of one straight section is fitted with air locks to facilitate internal exposures and bombardments. A small air lock with a 6-by-13-inch aperture has a probe mounted in it without an internal support. Loads up to ten pounds are plunged into the beam orbit on this probe. A larger air lock with an 18-by-20-inch aperture is used for loads up to 150 pounds. With this lock and its associated probe mechanism, targets can be mounted on a trolley car which travels into the vacuum system on support rails. Figure 2a is a photograph of a small type air lock and part of its probe assembly. Figure 2b is a photograph from the inside of a straight section showing a probe with a trolley and support rails. Figure 3 is a photograph of a test emulsion stack mounted on a probe. The piece of lucite taped on the end is the lip referred to above.

CHAPTER IV

NUCLEAR EMULSIONS - EXPOSURE AND PROCESSING

1. Nuclear Emulsions.

The recent development of nuclear emulsions that are sensitive to all charged particles has provided researchers with an excellent quantitative as well as qualtitative research tool. Nuclear emulsions are similar to ordinary photographic emulsions but differ in that they are thicker and have very high silver concentrations and rigid specifications as to purity, uniformity, and smallness of grains. Ionizing particles which penetrate the emulsions leave behind developable silver bromide crystals. The particle path appears as a row of black grains after development. The energy loss (by ionization of a particle) to the electrons of the emulsion crystals causes a dislocation in the crystal structure, making it a development center. The average energy loss per centimeter of path is

$$-\frac{dE}{dx} = \frac{4\pi e^4 z^2 NZB}{mv^2}, \tag{8}$$

where m is the electronic mass, v is the velocity and ze the charge of the incident particle, N is the number of atoms per cm^3 and Z the nuclear charge of material being traversed, and B is a function only of velocity in a given medium. Comparison of the characteristics of a track from an unknown particle with those of a known particle make track identification possible. The details of emulsion types and compositions, track evaluation, emulsion processing, and auxiliary techniques are covered in review articles by Beiser [17] and Stiller et al. [23] .

One of the most versatile emulsions for high-energy particle investigations is the Ilford G.5 type, which is sensitive to all charged particles regardless of their energy. These emulsions are supplied mounted on glass plates in thicknesses from 25 to 1200 microns of any size desired. The thicker emulsions are also supplied as stripped pellicles which can be packed together as a solid block. After exposure they may be separated, mounted on glass plates, and processed. A

stack of pellicles provides a large sensitive volume in which tracks can be followed from one layer to the next, a necessary requirement if detailed analyses of high-energy nuclear events are to be made.

In preparing for this experiment stacks of 2-by-4-inch 600-micron Ilford G.5 emulsions were used. Two holes were punched into the individual pellicles near the ends. The pellicles were than numbered and assembled between two pieces of 0.25-inch bakelite. The bakelite ends were bolted together by means of close-fitting bolts to insure that there was a known alignment of the pellicles and that they were closely packed. The stack was then wrapped in black paper and tape to make it lightight during subsequent handling and exposure to the beam. The method used in this experiment for alignment of stripped emulsions is given in a report by Goldhaber et al. [25] .

2. Internal Beam Exposure.

The assembled stack was mounted on a probe head in one of the smaller type air locks shown in Fig. 2a. They were oriented so that the beam particles entered one edge parallel to the plane of the emulsion. The stack was exposed to an integrated proton beam of about 10^7 particles. This resulted in a track density of about 10^5 per cm^2 in the region one inch from the edge that intercepted the greatest portion of the beam. The proton track density has the characteristics of an exponential decay across the plate. If the density is too low, there is only a slight probability of finding interesting events; if it is too high, there are so many tracks that accurate analysis or following of tracks is impossible.

During any exposure it is desirable to determine if the particle flux was of the desired value, to obtain an estimate of background radiation, and to determine effectiveness of shielding if part of stack is to be shielded. To satisfy these requirements test plates (50 or 100 microns thick) are exposed under conditions of geometry similar to the assembled stack before the regular exposure and (or) exposed with the emulsion stack. Test plates (50 microns) can be developed within an hour and a decision made as to whether additional exposure time is required. The small packages taped on the emulsion stack in Fig. 3 show

how test plates were used during a typical exposure of this experiment.

3. Processing Emulsions.

After exposure and before processing, the pellicles were marked by a grid system in order to facilitate the following of tracks through the stack. This was done by contact-printing a numbered grid system of one-millimeter squares upon the bottom of each pellicle. The grid system was oriented with the aid of the alignment holes that had been punched into the pellicles previously. The grid lines and numbers, reproduced by development, were visible when the bottom of the emulsion was brought into the focal plane of a microscope.

After the pellicles were marked, they were mounted on glass plates for processing. The development procedure varies with emulsion thickness. The exact details of chemical solutions, times, temperatures and steps in the development vary somewhat with the quantitative information that one expects to obtain from the emulsions. Some of the requirements influencing the choice of a procedure to be followed are:

(a) A favorable ratio of track grain density to background grains, so that even the thin tracks of singly charged particles at relativistic velocities can be followed with ease.

(b) A low level of track distortion, so that reliable multiple Coulomb scattering measurements may be made.

(c) Uniform development from surface to glass to permit grain density measurements that need not be corrected for track depth in the emulsion.

In this experiment we were concerned with the analysis of particles of relativistic velocities ($g_{min} \leq g < 1.4\, g_{min}$). A minimum amount of distortion and uniform development were therefore essential. We found that a slight modification of the Bristol development technique gave the most suitable results. The steps, times, and temperatures for this type of development are given in Table II.

Table II

Steps in Bristol Development Method

Stage of Development	Time		Temperature
Presoak	2.5	hours	5° C
Cold developer	2.5	hours	5° C
Dry hot stage	2.25	hours	18° C
Cool for	1	hour	18° to 5°C
Stop bath	2.5	hours	5° C

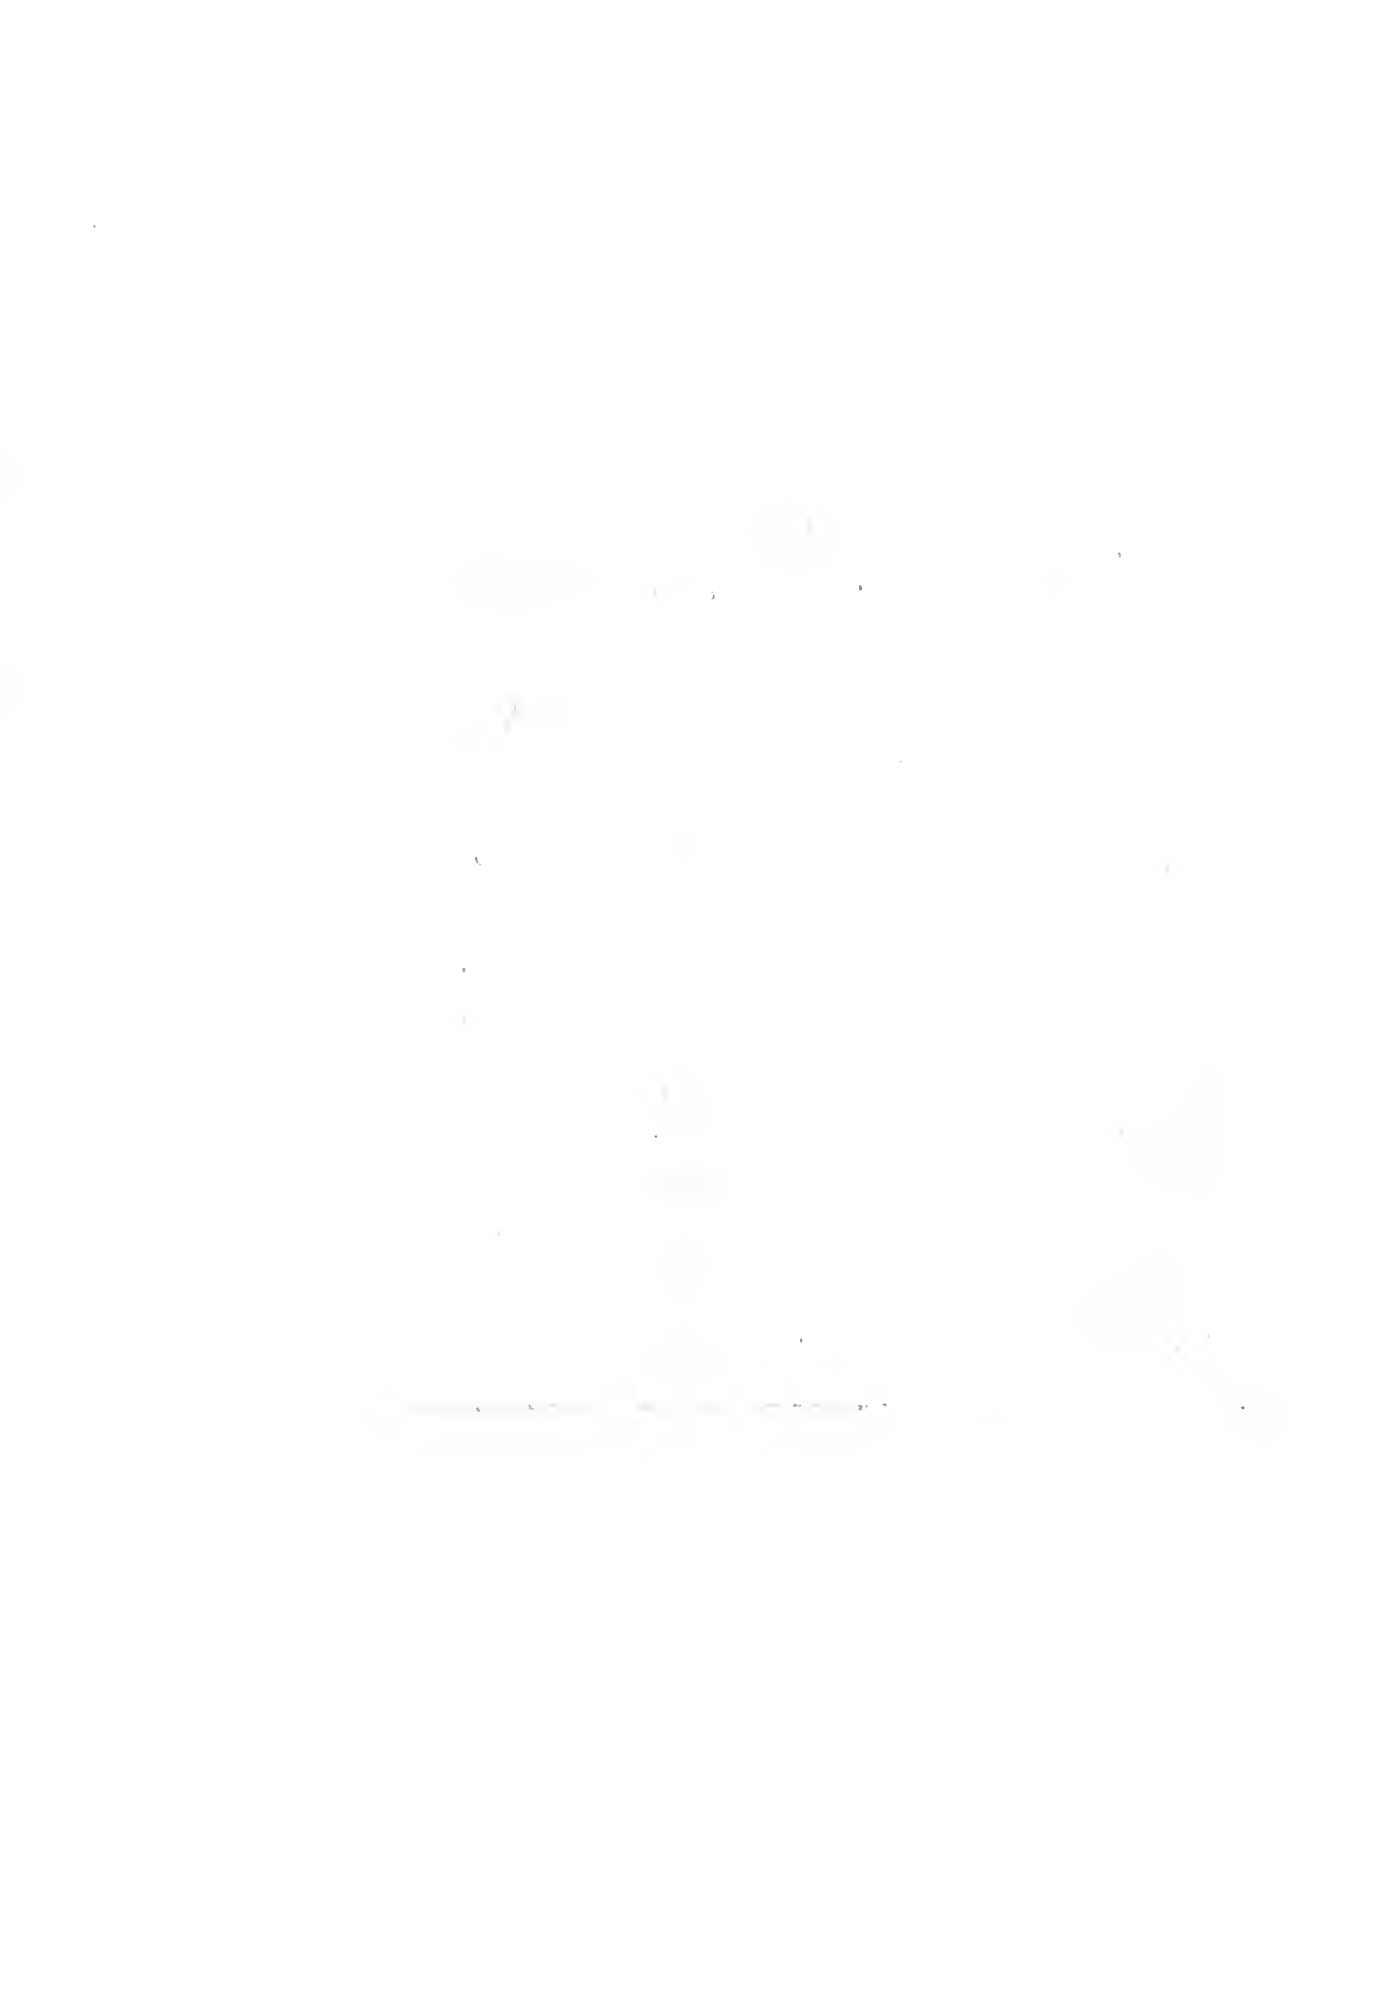
Fix	54	hours	8° C
Dilution	3	days	8° C
H_2O	2	days	5° C
Plasticize	2	hours	5° C
Alcohol dry	60	hours	5° C
Air dry	~24	hours	



CHAPTER V

EXPERIMENTAL METHOD

1. Experimental Nomenclature and Criteria.

In the study of nuclear interactions terms have been defined in different ways by emulsion workers. In the discussion of this experiment the definitions of Camerini et al. [3] are used. These definitions comprise the Bristol notation, which is in general use. Nuclear disintegrations are classified by the number and type of secondary tracks and the type, if known, of the primary particle. Secondary tracks are divided into three classes according to their specific ionization or grain density g. The grain density is compared with the grain density, g_{min}, of a singly charged particle at minimum ionization. Track classifications are as follows:

(a) Thin Tracks, $g_{min} \leq g < 1.4\ g_{min}$ (Represented by n_s)

(b) Grey tracks, $1.4\ g_{min} < g < 6.8\ g_{min}$ (Represented by N_g)

(c) Black tracks, $g > 6.8\ g_{min}$ (Represented by N_b)

The thin tracks as defined in (a) are caused by "shower" particles, which are comprised of protons with kinetic energies greater than 500 Mev, pions with kinetic energies greater than 80 Mev, or heavy mesons of intermediate energies. (The number of heavy mesons is very small.) The grey tracks are produced by protons with energies between 25 and 500 Mev. These protons are for the most part due to recoils produced in the early stages of the disintegrations, a process previously discussed in Chapter II. Some grey tracks result from pions of kinetic energy less than 80 Mev, deuterons, and tritons. Pions form less than 5% of the grey tracks [3]. Black tracks are primarily caused by the low-energy evaporation particles, protons, deuterons, tritons, and alpha particles. They are emitted in the final stages of the disintegration.

The sum of the grey and black tracks is designated by N_h, the number of heavy tracks. A star is then characterized by $N_h + n_s$,

followed by a suffix to denote the nature of the particle producing the disintegration (i.e., π for a pion, p for a proton, n for a neutron or an unidentified neutral, and α for alpha particle). For example, a 7 + 2p star means that there are seven heavy and two shower tracks originating from a star caused by an incoming proton.

As previously states for stars classified by the Bristol notation, n_s included both pions with kinetic energies greater than 80 Mev and protons with kinetic energies greater than 500 Mev. The number of emitted pions with energies below 80 Mev is small and is equal, in the first approximation, to the number of emitted protons with energies greater than 500 Mev. The value of n_s as observed can therefore be assumed to be an indication of the number of charged mesons emitted. This assumption has been made by cosmic-ray workers [4] and is also made in this experiment. Observations of Fowler et al. [7] at the Cosmotron indicate that few charged mesons are produced with energies below 80 Mev, thus lending further validity to the assumption.

2. Experimental Procedure.

In order to study the results of interactions at known primary energies, stacks of 2-by-4-inch 600-micron Ilford G.5 stripped emulsion pellicles were exposed to the internal beam of the Bevatron at three energies--3.2, 4.8, and 5.7 Mev. Exposures were made on a plunging probe and the modified Bristol development was used. Minimum ionization was determined by grain-counting beam proton tracks, and was found to be 26 grains per 100 microns.

A plate at each energy was selected for this study. The plates were "area-scanned" under 6 x 53 power on a Leitz microscope with an oil-immersion objective lens. Overlapping fields of view were examined to insure complete coverage. Since there is no selective choosing of any particular star size, systematic area scanning gives a representative sample of all stars produced that have two or more prongs. (The efficiency for detection of the one-pronged events is very low unless the plates are scanned along and in the direction of the beam tracks.) Whenever a star was found, it was examined to determine if it was caused by a beam proton. If it was,

the star was then analyzed under 12 x 100 power and classified according to the numbers of heavy and shower tracks. Each track with a specific ionization at or slightly above minimum was tentatively identified as one belonging to a shower particle. Those tracks above minimum were grain-counted to a statistical accuracy of less than 10% and compared with 1.4 g_{min}. The identity of the track--as one caused by a heavy particle or a shower particle--was thereby established. Each plate was scanned until 114 primary-beam stars were found.

As a secondary experimental objective, all prongs except the thin tracks were followed to their ends or until they left the plate. Thin tracks were followed for two to three millimeters. The secondary objective was a search for possible interesting events such as double stars (a double star is one in which the incident nucleon has been emitted from another star), hyperon decays, and heavy-meson decays.

CHAPTER VI

EXPERIMENTAL RESULTS

1. Yield Curves for $\overline{n}_s$ and $\overline{N}_h$.

The average values of the numbers of shower and heavy particles, $\overline{n}_s$ and $\overline{N}_h$, are plotted on Fig. 4. Each point represents observations on 114 stars, and the indicated error is the standard deviation based on the number of tracks recorded. For comparison, results of Camerini et al. [3] are plotted in dashed lines. Experimental curves show expected increases with primary particle energy. The general shapes are in fair agreement with the results found in cosmic-ray stars, but the values are somewhat lower. For example, at 5.7 Mev experimental values of $\overline{n}_s$ and $\overline{N}_h$ are 1.6 and 11.5; the curves from cosmic-ray stars give values of 2.55 and 13.0.

For that portion of the energy spectrum investigated both yields appear to increase exponentially with the incident nucleon energy. Only a narrow (narrow when compared to the spectrum available in cosmic rays) portion of the primary particle energy spectrum has been used, however, and the statistics are not good enough to make any positive statement in this regard.

The lower $\overline{n}_s$ yield in this experiment might be expected because the cosmic-ray primaries were an admixture of pions and protons. In the center-of-mass system of a nucleon and pion with the nucleon stationary and the pion incident, there is more energy available for meson production than there is in a similar system with an incident proton. This is evident from the expression for the ratio of the amount of energy available for interaction (in the center-of-mass system) with an incoming pion to that available with an incoming proton. If the pion and proton have the same energies, the ratio reduces to

$$\frac{W_{\pi\,\mathrm{inc}}}{W_{p\,\mathrm{inc}}} \cong \frac{(1 + 2\,\gamma_p)^{1/2} - 1}{(2 + 2\,\gamma_p)^{1/2} - 2},$$

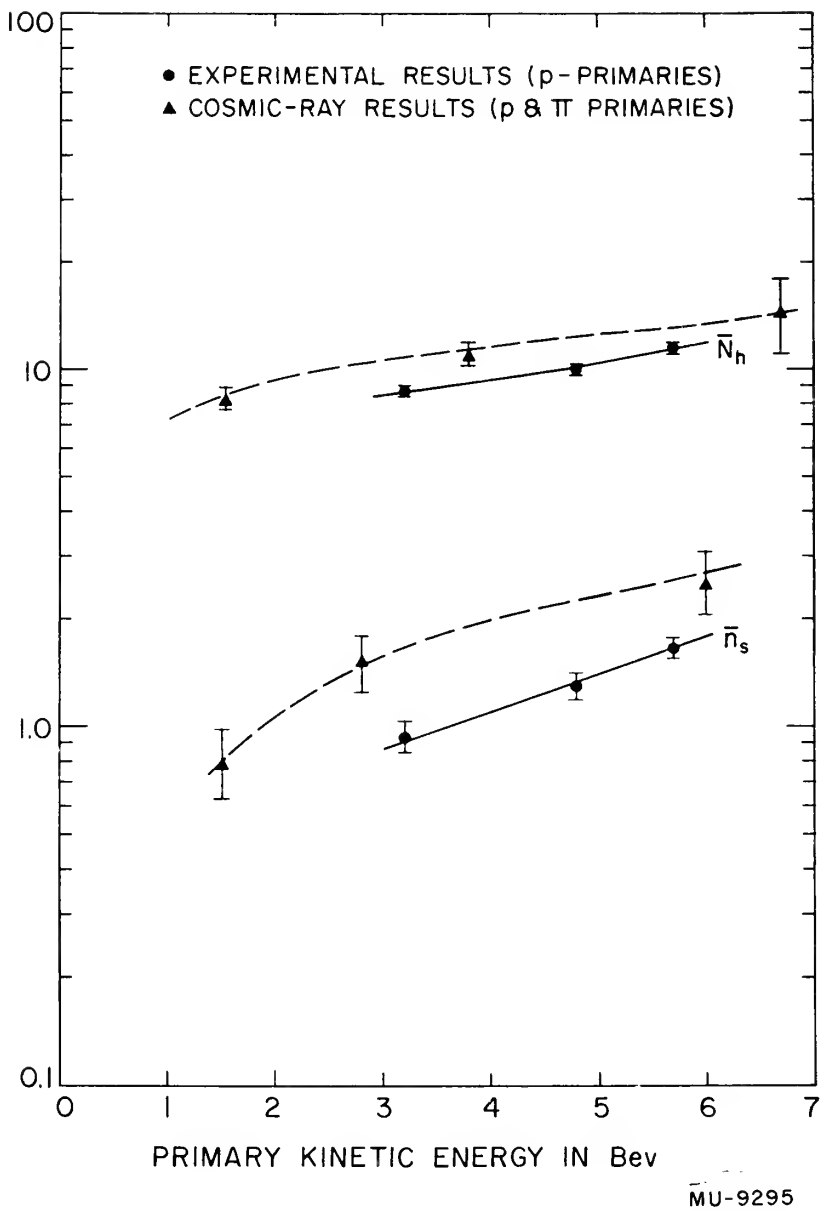


Fig. 4 Comparative plots of the average number of heavy prongs and the average number of shower particles versus kinetic energy of primary particles.

where

$$\gamma_p = \frac{E_p}{M_p C^2} \quad . \tag{9}$$

For a primary energy of 6 Bev the ratio is 1.65. From the experimental curve for incident protons $\overline{n}_s$ is found to be 1.8 at 6 Bev. If cosmic rays were assumed to contain 50% pions, $\overline{n}_s$ would equal (1.8/2)(1 + 1.65) or 2.4. At 6 Bev, curves of shower-particle production in stars produced by cosmic rays at 11,000 feet show $\overline{n}_s$ to be 2.5.

A second possible contribution to the difference between the two observations may be in the measurement of the primary particle energy. In this experiment the energy of the Bevatron beam is well known, but cosmic-ray primary energies have been determined by multiple-scattering measurements and are subject to error. From a discussion of this point with cosmic-ray workers [21] I was advised that they feel that their energy measurements are accurate within five percent in the energy region below 10 Bev. From this it can be concluded that differences must be caused by the pions among the cosmic-ray primaries. The exact pion contribution cannot be readily determined.

2. Shower-particle Multiplicity.

The first conclusion stated in the previous section is further substantiated by the plots in Figs. 5 and 6. These plots represent the observed multiplicities rather than the average values discussed previously. Figure 5 contains comparative normalized plots of the shower-particle multiplicity as observed for cosmic-ray primaries [3] in the energy range of 1.9 to 4.3 Bev and the multiplicity as observed experimentally at 3.2 Bev. Figure 6 shows the same observations at cosmic-ray energies between 4.3 and 9.4 Bev and at energies of 4.8 and 5.7 Bev in this experiment. These plots are not exact comparisons since the observations in this experiment were made at specific known energies and the cosmic-ray observations covered a relatively wide band. The experimental energies, however, represent fair medians of the cosmic-ray energy bands. The proportion of stars

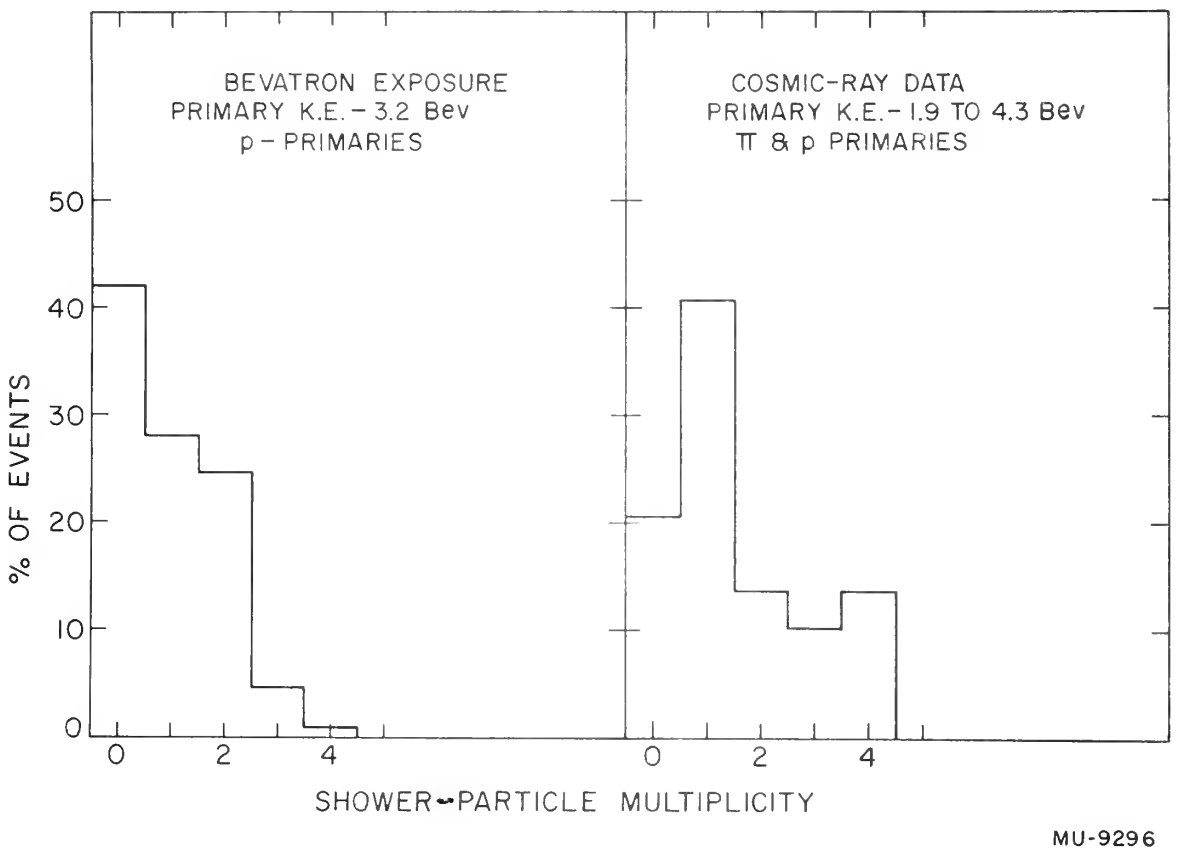

Fig. 5. Comparative normalized distributions of number of events versus shower-particle nultiplicity.

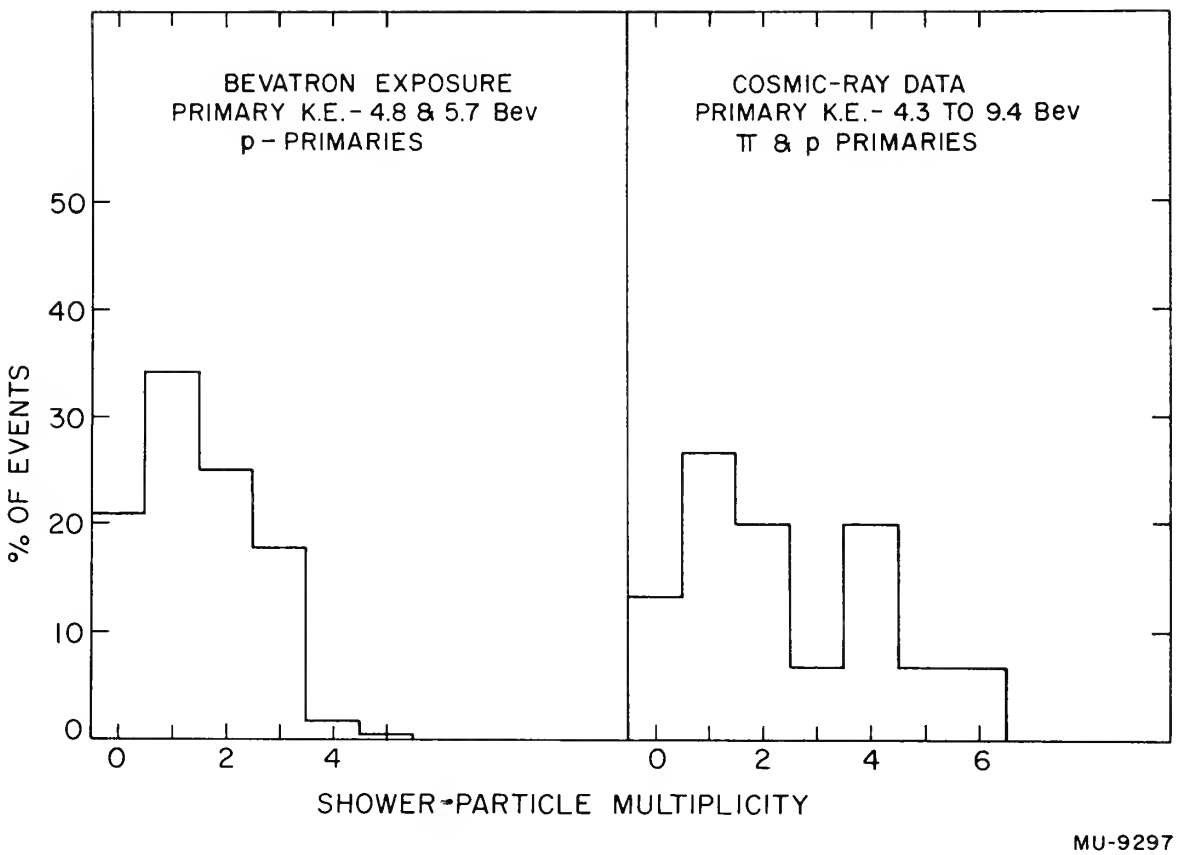

Fig. 6. Comparative normalized distributions of number of events versus shower-particle multiplicity.

with n_s equal to zero is greater by a significant amount in each case with "p" primaries (this experiment) than with "π and p" primaries (cosmic-ray observations). This then, is additional evidence that in the mechanism of individual collisions within the atomic nuclei a meson is more effective than a nucleon of the same energy in producing additional mesons.

The two figures indicate another feature of meson production--the wide spread in multiplicity at any given primary energy. This would be expected from the statistical nature of meson production, and indicates very definitely that shower-particle multiplicity in an individual event is an unreliable indication of primary particle energy in the portion of the incident energy spectrum investigated. With extremely high-energy cosmic-ray primaries upwards of 30 mesons are produced. In these collisions the number of mesons is used to estimate the primary energy.

3. Distribution of Star Sizes.

Figures 7b - 7d are normalized histograms of the number of events with N prongs versus the number of prongs at the primary energies of this experiment. Figure 7a is a similar plot of data at 1 Bev found by Lock et al. [20] at Birmingham. (The Birmingham data have been included as additional information on how the general shape of the prong distribution changes with primary energy.) An interval of four prongs has been used on the abscissa in order to reduce the statistical fluctuations that would result from the small number of stars used for this analysis.

The histograms show peaks in the 4- to 8-prong interval. This range represents the maximum number of prongs from the complete breakup of the light nuclei of the emulsion; i.e., carbon nitrogen, and oxygen. The numerical value at the maximum decreases with increasing energy. The change in distribution results from the presence of more stars with greater numbers of prongs. These larger stars are due to the more complete breakup of the heavier nuclei, silver and bromine. The increase in the number of mesons produced

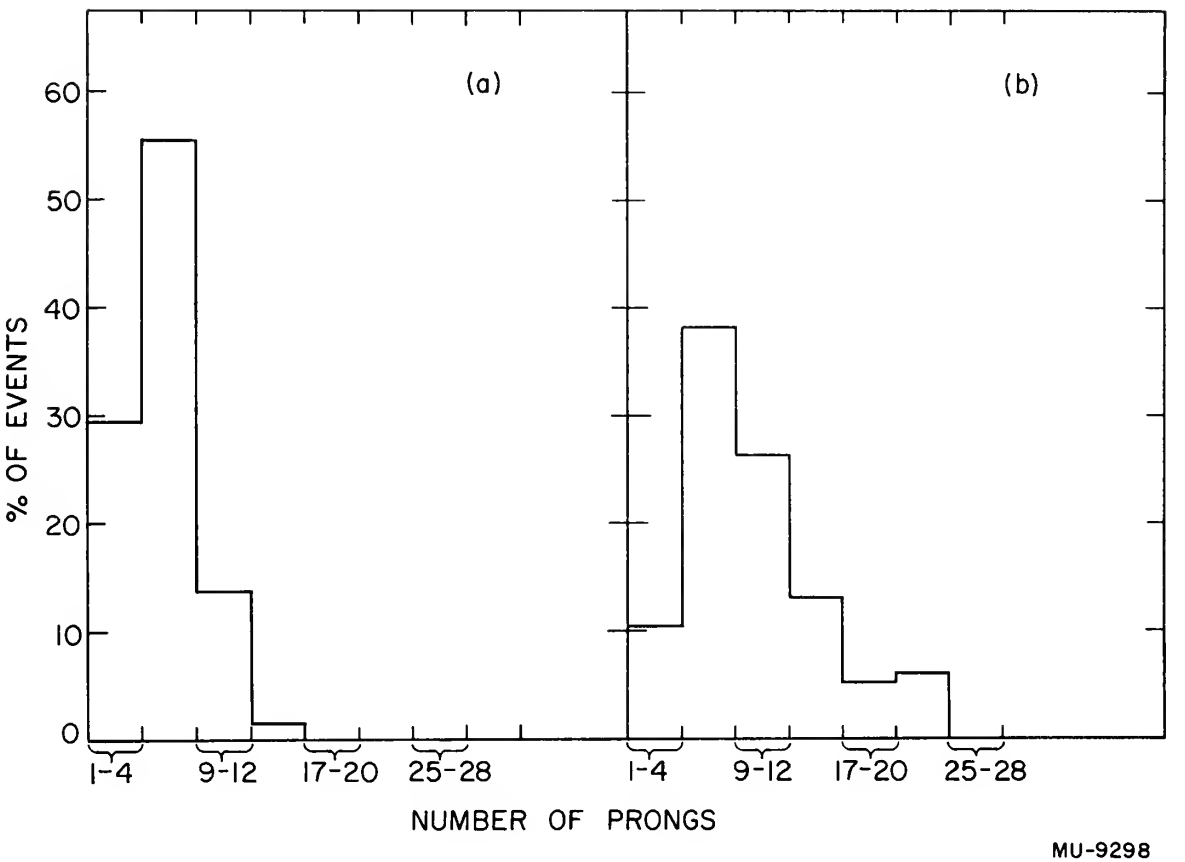

Fig. 7a. Normalized histogram of number of events with N prongs versus number of prongs. Primary energy 1.0-Bev. From data of Lock et al. [20].

7b. Primary energy 3.2-Bev.

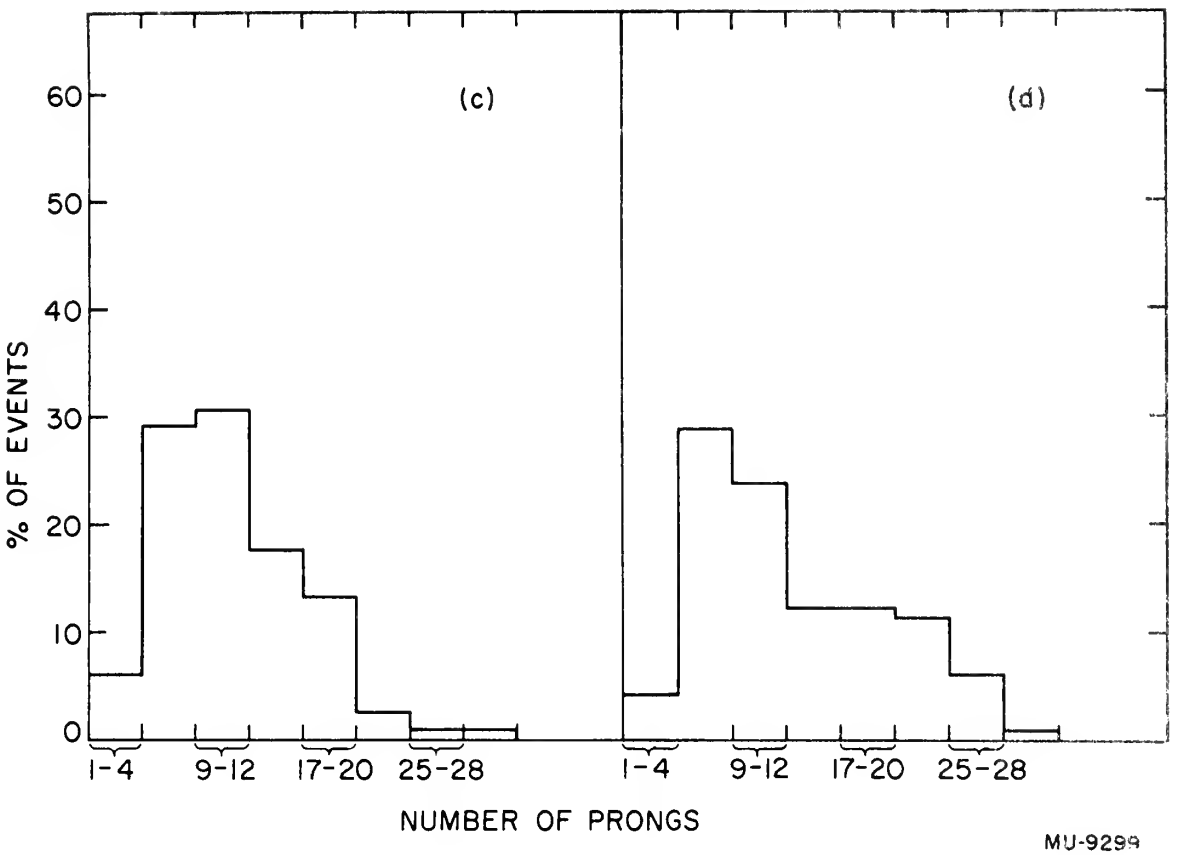

Fig. 7c. Normalized histogram of number of events with N prongs versus number of prongs. Primary energy 4.8-Bev.

7d. Primary energy 5.7-Bev.

NO OF EVENTS

contributes negligibly to the larger stars because of the small change in multiplicity. The peak is broadened on the side towards the greater number of prongs and there is a slight indication that a second peak is developing in the 17- to 20-prong interval at 5.7 Bev. This peak might become apparent if the investigation were extended to higher primary energies. With good statistics and higher primary energies, it is a reasonable assumption that one will be able to see definite peaks representing the breakup of the atoms of different mass number. The increase in star size with primary energy can be seen in Table III.

Table III

Average Number of Prongs per Star

Primary Energy in Bev	Average Number of Prongs
1.0 (a)	5.7
3.2	9.6
4.8	11.3
5.7	13.1

a The data of Lock et al. [20] include one-prong stars, but they have been excluded in this computation of averages because no one-prong stars were recorded in this experiment. Lock's one-prong stars were found for the most part by scanning along the track (Chap. V, Sect. 2).

4. Comparison of Disintegrations of Light and Heavy Nuclei.

A comparison of the average multiplicity of n_s with N_h is also of interest in order to observe any effect that nuclear size might have on shower-particle production. Stars with N_h greater than eight must generally result from the disintegration of the silver and bromine nuclei, while smaller stars can be due to both the light and heavy nuclei within the emulsion. The exact proportional contributions from the heavy and light elements to stars with $N_h \geq 9$ cannot be easily

determined because of the statistical processes involved and the variation in the thermal excitation energy available after the collision. The energy available varies with the number of mesons produced and the number of particles that escape before evaporation starts.

Figure 8 is a plot of average multiplicity as a function of the primary energy for two classes of stars, $4 \leq N_h < 9$ and $N_h \geq 9$. Cosmic-ray observations in this energy range are included for comparison. There is no significant difference between the two classes of stars; the curve for the stars with $4 \leq N_h < 9$ shows a slightly greater multiplicity, but the standard deviations of all points on both curves overlap about 50 %. Cosmic-ray workers [4] had overlapping points below 10 Bev without a definite trend in either set of points, but they noted that $\bar{n}_s$ was greater for the heavy nuclei at 14 Bev — 4.3 for heavy nuclei and 2.4 for light.

Figure 9 is a plot similar to Fig. 8, but only those events in which the shower-particle multiplicity was equal to or greater than unity are included. There is no significant difference between the two plots, and the same comments apply. Figure 8 undoubtedly included events in which only uncharged pion (s) were produced. These events would be excluded for the most part in Fig. 9, and one would expect differences in the two curves only if there were a significant difference in the numbers of charged and neutral mesons produced.

It may be possible that secondary generation would be more evident in heavy nuclei, because of the greater number of mean free paths to be traversed before escape, and would thereby cause the shower-particle multiplicity to be increased in these stars. On the other hand, reabsorption of mesons in the parent heavy nucleus will tend to reduce the number of emitted mesons and increase the number of recoiling nucleons. It is reasonable to assume that this reabsorption is the more important process in the energy range of this experiment, and the secondary generation process gains in importance at energies greater than 10 Bev. Reabsorption may explain stars that have a large value for N_h but a small n_s when compared with their

AVERAGE SHOWER PARTICLE SPECTRUM

respective average values.

5. General Observations.

It is interesting to note some qualitative general observations made during this study. These observations concern angular distributions and secondary experimental objectives.

The shower particles were strongly concentrated in the beam direction. Occasionally a track from a star in which there was multiple production would extend in the backward direction. The latter tracks were not collimated parallel to the beam direction to the same degree as were the former.

There was, in general, an isotropic distribution of the black tracks, but in several stars with more than fifteen tracks there were three or more black tracks that almost overlapped. It appeared that one section of the nucleus had gained momentum in a certain direction and that this fragment broke into more elementary particles as it left the nucleus. This phenomenon was exhibited at two or three points in the largest stars, and might be considered to be due to some kind of local heating. Fujimoto and Yamaguchi [8, 9], in their discussions of nuclear evaporation, consider local heating to be extremely rare, but their predictions did not include the potentially high energies available within a nucleus penetrated by 6 Bev protons. Similar phenomena have been reported in cosmic-ray stars [11].

In the search for interesting events by following prongs, eleven double stars were found, and seven low-energy pions were seen ending and forming σ-stars. No positive-pion, heavy-meson, or hyperon decays were noted that could be positively identified. With regard to the pions, these results support the statements of Brown et al. [2], who found that 95% of the slow mesons produced in stars are negatively charged. This result can be attributed to the effect of nuclear charge, which will cause positive particles to be emitted with greater kinetic energy than negative ones. Therefore they will escape from the emulsion except in rare cases.

CHAPTER VII

THEORETICAL COMPARISONS

1. Fermi Model.

Fermi used his statistical model to calculate meson production at Cosmotron energies. His calculations have been extended to compute the expected meson production at the beam energies of this experiment. The complete calculations have been carried out for proton-neutron (p-n) and proton-proton (p-p) collisions at each energy. Details of the calculations are similar to those described in Fermi's papers [5, 6], discussed in Chapter II. An assumption is made in tabulating expected probabilities that there is a like number of p-n and p-p collisions. The final results of the calculations, together with experimental observations, have been summarized in Table IV.

The Fermi statistical model shows fair agreement for average production, but the rate of increase with energy is lower. This could be accounted for in part by the restriction, $n_s \leq 3$, in the calculations. The observations at 5.7 Bev include five stars with $n_s > 3$. Exclusion of these events would reduce the observed multiplicity to 1.46 ± 0.12, which compares favorably with the computed 1.44. There is less agreement in the actual percentages of stars with the various values of n_s, but general shapes of the distributions are comparable.

2. Lepore Model.

Lepore made some changes to the Fermi model in postulating his model [18]. He has made calculations to determine the expected production at 2.5, 3.9, and 4.71 Bev (center-of-mass system). In the laboratory system of two colliding nucleons, one of which is at rest, 6.3 Bev is equivalent to 3.9 Bev in the center-of-mass system.

Table IV

Observed and Calculated Shower-Particle Multiplicity Percentages--Fermi Model

Energy in Bev	n_s	Extension of Fermi's Calculations a	Experimental Observations
3.2	0	20	42
	1	47	28
	2	29	25
	3	4	4
	4	--	1
Av.	$\overline{n}_s$	1.17	0.94 ± 0.09
5.7	0	16	25
	1	41.5	38
	2	35	20
	3	7.5	17
	4	--	0
Av.	$\overline{n}_s$	1.34	1.3 ± 0.11
5.7	0	14	17
	1	38	31
	2	38	30
	3	10	18
	4	--	3
	5	--	1
Av.	$\overline{n}_s$	1.44	1.62 ± 0.11

a In the computation of the percentages for each value of n_s the tabulated number represents the shower tracks that would actually be observed, not the number of pions created. The numbers in column 3 for $n_s = 2$ include the following production schemes: pp + -, nn ++, pp + - 0, nn ++ 0, and pn + - 0. (The +, - and 0 refer to the charge of the created mesons.)

Table V is a summary of the expected pion production at this energy from Lepore's paper.

Table V
Pion Production at 6.3 Bev--Lepore Model

Pions Produced	Lepore's Calculations for 6.3 Bev	Observed n_s Percentage at 5.7 Bev
0	12	17
1	38	31
2	40	30
3	10	18
4	--	3
5	--	1
Average	1.48	1.62 ± 0.11

Lepore's computations were for indistinguishable particles; therefore the figures in column 2 of Table V include positive, negative, and neutral pions. When equal distributions of the three types of pions are assumed, tracks from only two-thirds of the particles could be observed in emulsions. The observable average would be 1.0, which is to be compared with 1.9 from the experimental curve at 6.3 Bev.

3. Other Theories.

The other theories of meson production discussed in Chapter II do not yield easily to calculation in the energy range of this experiment. Average multiplicities from the theories of Heitler and Heisenberg have been plotted by Camerini et al. [4]. Table VI contains the values obtained from these curves.

Table VI

Average Shower-Particle Multiplicities;
Heitler and Heisenberg Theories

Primary Kinetic Energy in Bev	Average shower-particle multiplicity, $\bar{n}_s$				
	Heitler Theory	Heisenberg Theory a			Observed
		K = 1.0	K = 0.7	K = 0.3	
3.2	2.0	2.1	1.7	0.9	0.94
4.8	2.9	2.6	1.9	1.1	1.3
5.7	3.1	3.0	2.1	1.2	1.62

a K is the degree of inelasticity of the collision. A completely elastic collision is denoted by K = 0.

The plural theory of Heitler gives values that are high compared with the observations. The data derived from Heisenberg's theory appear to be in fair agreement with the experimental results if the K-value is near 0.4. It is also interesting to note that the Heisenberg theory postulates multiple production, as does the Fermi theory. There is not sufficient information in the theories to determine and compare the predicted percentage distributions of the particles, as could be done with the Fermi and Lepore theories.

4. General Comment.

The experimental results and the discussion of the various theoretical approaches to the problem of meson production indicate that there are many questions to be answered in this field. More pion-nucleon and nucleon-nucleon experiments conducted in the 1- to-10-Bev energy range would shed much light on the problem. This experiment appears to give some evidence of the correctness of one phase of the Fermi theory, but more definite conclusions must await experimental data with better statistics and a more complete and detailed analysis of all the products of nuclear disintegrations. The analysis needs to include the identification and the energy spectrum of all products, the directions of emission, the charge distributions, and the identification of target nuclei. Only the joint efforts of many experimenters for an extended time may furnish the answers.
